1 Background

Let $X = \{x_1, \dots, x_N\}$ a collection of N points. Now, lets suppose that the features of x_j are updated, and lets call x_j^* the updated point. Lastly, lets define $X_{-j} = \{x_1, \dots, x_{j-1}, x_{j+1}, \dots, x_N\}$.

The posterior before x_j moves, and using $P(\Theta)$ as the prior is

$$P(\Theta | X) \propto P(X | \Theta)P(\Theta)$$

,

where $P(X | \Theta) = \prod_i^N P(x_i | \Theta)$.

Now, after x_j moves to x_j^* , the posterior is

$$\begin{aligned} P(\Theta | X_{-j}, x_j^*) &\propto P(X_{-j}, x_j^* | \Theta)P(\Theta) \\ &\propto P(X_{-j} | \Theta)P(x_j^* | \Theta)P(\Theta) \\ &\propto \frac{P(X | \Theta)}{P(x_j | \Theta)}P(x_j^* | \Theta)P(\Theta) \\ &\propto \frac{P(x_j^* | \Theta)}{P(x_j | \Theta)}P(X | \Theta)P(\Theta) \end{aligned}$$

which can be written as,

$$P(\Theta | X_{-j}, x_j^*) \propto \frac{P(x_j^* | \Theta)}{P(x_j | \Theta)}P(\Theta | X) \quad (1)$$

Now, if we instead of considering one data point x_j , we consider a batch of S data points $X_J = \{x_j, x_{j+1}, \dots, x_{j+S-1}, x_{j+S}\}$ that moved from x_{j+k} to x_{j+k}^* , for $k = 0, \dots, S$. And lets define $X_{-J} = \{x_1, \dots, x_{j-1}, x_{j+S+1}, \dots, x_N\}$. Then, Eq. 1 for the batch of S data point and because the prior $P(\Theta)$ gets canceled, can be written as,

$$P(\Theta | X_{-J}, X_J^*) \propto \frac{P(\Theta | X_J^*)}{P(\Theta | X_{-J})}P(\Theta | X) \quad (2)$$

Inspired by the work done in [1], we assume that we approximate the posterior using **variational inference**. Also, we assume that $P(\Theta)$ is an exponential family distribution for Θ with sufficient statistic $T(\Theta)$ and natural parameter ξ_0 . We suppose further that if $q(\Theta)$ is the approximate posterior obtained using variational inference, then $q(\Theta)$ is also in the same exponential family with a parameter ξ such that

$$q(\Theta) \propto \exp(\xi \cdot T(\Theta)). \quad (3)$$

Similar to [1], when we make this assumptions the update in Eq. 2 becomes

$$P(\Theta \mid X_{-J}, X_{-J}^*) \approx \exp([\xi - \xi_{-J} + \xi_{-J}^*] \cdot T(\Theta)) \quad (4)$$

where ξ is the natural parameter of $q(\Theta) \approx P(\Theta \mid X)$, and ξ_{-J} and ξ_{-J}^* corresponds to the natural parameter of $q_{-J}(\Theta) \approx p(\Theta \mid X_{-J})$ and $q_{-J}^*(\Theta) \approx p(\Theta \mid X_{-J}^*)$ respectively.

Using this approach, we can update the posterior when data "moves" without the need to go through the whole dataset, instead we just need to go through the data points that moved to obtain ξ_{-J} and ξ_{-J}^* .
